ABSTRACT: In this article I examine whether the academics reward policy must correlate positively with the published number of articles per co-author, number of pages and journals reputation. This is accomplished by estimating a non-linear model with a panel data from 168 economics journals covered in the ISI-Web of Knowledge database (58825 articles). The data reinforces the conjecture that published article value is slightly increasing with the number of co-authors and is proportional to the number of pages. The data also suggests that there are 4 distinct groups related to journal quality that I name A, B+, B and B-.

KEYWORDS: Co-authorship, Value of articles, Assessment of output.

I. INTRODUCTION

OECD countries devote an enormous quantity of resources to scientific activities, an important proportion of these activities being performed by academics. To promote an efficient resource allocation, more productive academics must be encouraged to the detriment of their counterparts. It is therefore important to quantify the value of academics' output. As a rule, in market economies, price is the measure of output value. However, academics are primarily devoted to basic science investigation that

the market is unable to price (e.g., Freeman and Soete, 1997). Hence, it is essential to develop alternative ways of assessing scientific output.

Universities have been using a panel of judges to compare candidates to a job position or a funding opportunity. But economic science has numerous different areas of expertise, making it difficult to include in the panel experts in all areas of candidates' specialisation. In addition, human beings are biased in favour of those individuals that are similar to them, Webster (1964). To overpass both of these difficulties, the articles published in scientific journals that implement blind refereeing are more and more important in the evaluation of academics.

With the data from 140 USA academic economists, Sauer (1988) provides empirical evidence that academic salaries are significantly increasing with the number of published articles, the number of published pages and journal reputation (divided by the number of co-authors). Among others, Ragan *et al* (1999) corroborate these findings.

In this paper, I intend to examine whether this reward policy is correct. More precisely, I intend to evaluate the hypotheses that there is not a positive correlation between the number of co-authors and article value, and that there is a positive and proportional correlation between pages and article value.

Although these issues have been partially addressed in the literature (e.g., Hudson, 1996, Heck and Zaleski, 1991, Johnson, 1997, Laband and Tollison, 2000; Hollis, 2001, Coupé, 2004), my perspective and methodology are new. First, I use an extended panel data sample (with approximately 60000 articles). Second, I estimate the explicative importance of the variables simultaneously. Third, I use a non-linear model (iso-elastic) where parameters are estimated using Ordinary Least Squares

(*OLS*) and Bootstrapping (Efron, 1979; Efron and Tibshirani 1993) implemented in MS Visual Basic TM. This last issue, although technical, seems to me important because non-linear panel data models are increasingly required in economics and “the maximum likelihood estimator in non-linear panel data models with fixed effects is widely understood to be biased and inconsistent” (Greene, 2002: 1). In contrast, *OLS* estimators are centric, efficient and easily understood.

Given that the primary objective of publication is the diffusion of knowledge, it is acceptable to credit more value to the articles that were cited more often (Laband and Sophocleus, 1985). This association being accepted, it is possible to evaluate the hypotheses with historical data downloaded from the ISI Web of knowledge.

II. THE EMPIRICAL MODEL

The hypothesis that article value is positively correlated with journal reputation, the number of co-authors and the number of pages, results from the conjectures that referees are consistent over time in the evaluation of articles (i.e., rankings are stationary, Vieira, 2004), that each author introduces a different point of view in the article that enlarges its value, and that referees, due to space limitations, are exigent on the relevance of each page expurgating the articles from all non-essential text (Sauer, 1988).

Since the value of an article published in a top-ranking journal is, on average, higher than its counterpart (otherwise, it would not be a top-ranking journal), it seems adequate to assume that co-author and page effect in article value is relative to the journal average value. An adequate functional form of a model is then the exponential. The value (impact) c of an article published in the journal j with a co-

authors and p pages after t periods since publication will be (where ε is a random part with the expected value equal to 0):

$$c = \hat{c} + \varepsilon = g(j) \cdot a^\alpha \cdot p^\beta \cdot t + \varepsilon \quad (1)$$

The impact is proportional to t because citations occur as an arriving process.

The function $g(j)$ condenses the fixed-effect of the journal j being a measure of the average value of a single authored page published in the journal j (see table 1 and table 2).

The journals fixed effect are modelled with dummy variables. As *OLS* estimators integrate the “average” point, fixed effects are easily estimated using this property:

$$g(j) = \frac{\bar{c}_j}{\bar{a}_j^\alpha \cdot \bar{p}_j^\beta \cdot \bar{t}_j} \quad (2)$$

Estimating the fixed-effects this way guarantees that substituting the average value of the explicative variables in the model (1) results in the journal average impact per article.

III. DATA COLLECTION

Panel data was downloaded from the ISI Web of knowledge site isi4.newisiknowledge.com in July 2005. I selected all articles published in the 11 year period between 1986 and 1996 in journals classified as "Social and Behavioural Sciences > Economics" (232 journals) and whose data is downloadable from the “ISI Web of knowledge” (168 journals). I selected the time span between 1986 and 1996 because “approximately 2/3 of all citations occur 13 years after the paper being published”, Vieira (2004). The ‘excluded’ journals have a low ‘Impact Factor’.

The collected data includes 58825 articles from 168 journals that, on average, were cited 12.37 times in the time span between the day of publication and July 2005, have 1.60 co-authors and 15.50 pages. The distribution of the number of times each article is cited approximates the exponential negative distribution function, with 20.0% being never cited (see fig.1). Engle and Granger (1987) is the highest impact article (cited 3129 times).

The distribution of co-authorship approximates the exponential negative distribution function as well, with 53.6% of the articles being single authored, 35.0% having two co-authors, 9.7% having three co-authors, 1.4% having four co-authors and the remaining 0.3% having 5 or more co-authors (the maximum is 22 co-authors).

The distribution of pages approximates the log-normal distribution function where 86.6% of the articles have between 4 and 25 pages (see fig. 2) and the maximum is 216 pages. Zero page articles are assumed to be database errors (0.1%) and are excluded from the sample.

In the sample, the journal with higher average number of citations is *Econometrica* with 66.97 citations per article, and the one with lower average number of citations is *Politicka Ekonomie* with 0.05 citations per article (see table 2).

Similar to Hudson (1996), I observe that during this 11 years time span there is a significant increasing tendency in the number of co-authors, a , and pages, p (t -statistics in parentheses):

$$\hat{a} = 1.603 + 0.0219 \cdot (t - \bar{t}), R^2 = 0.83\% \quad (3)$$

(502.8) (22.2)

$$\hat{p} = 15.503 + 0.237 \cdot (t - \bar{t}), R^2 = 0.77\% \quad (4)$$

(431.0) (21.3)

This seems to be a co-evolution since on average an additional co-author adds approximately one page to the article:

$$\hat{p} = 13.962 + 0.961 \cdot a, \quad R^2 = 0.73\% \quad (5)$$

(169.2) (20.8)

For a study of the patterns of co-authorship, see Sutter and Kocher (2004).

IV. ESTIMATION PROCEDURE

The explicative variable and the functional form of the model being known, one needs to estimate the magnitude of the parameters and to test their significance.

Let e_i be the deviation from the observed to the estimated model:

$$e_i(\alpha, \beta) = c_i - \hat{c}_i(\alpha, \beta) = c_i - g(j, t) \cdot a_i^\alpha \cdot p_i^\beta \cdot t_i \quad (6)$$

The unknown parameters α and β are estimated by minimizing the sum of squared deviations:

$$R(\alpha, \beta) = \sum_i [c_i - \hat{c}_i(\alpha, \beta)]^2 \quad (7)$$

Observe that the model is non-linear and non-linearisable because the data contains articles with zero impact (20.0%). To overcome this difficulty, I use a computational procedure implemented in MS Visual Basic 6.0™ to minimize the expression (7) numerically. As there are just two variables, I use a simple algorithm: I repeat the one variable independent optimisation until α (alpha) and β (beta) stop varying (see fig. 3).

The results of the estimation procedure are:

$$\hat{\alpha} = 0.237; \quad \hat{\beta} = 1.012; \quad R^2 = 20.88\% \quad (8)$$

The statistical importance of the model variables is related to the percentage of the sample variance that is reduced by the variables. The journal fixed-effect and the time span reduce the variance by 15.41%, the number of co-authors reduces the variance by 0.47%, and the number of pages reduces the variance by 5.00%. The total reduction is by 20.88%.

V. TESTING ESTIMATES STATISTICAL SIGNIFICANCE

Knowing the distribution function of the model stochastic term and the estimators' algebraic form, it is straightforward to obtain parameter statistics. But the estimator is obtained above through a minimization algorithm and the distribution function of the model stochastic term is not known. An ideal tool to be used in this situation is bootstrapping.

Bootstrapping assumes that statistical properties of the sample are identical to those of the population, being adequate to compute the statistical properties of the estimator by repeatedly re-sampling with reposition the data (see, Efron, 1979; Efron and Tibshirani 1993). I represent the bootstrapping algorithm in Fig. 4 and the estimators' frequency density distribution with 3000 re-samplings in Fig. 5.

Using 3000 re-samplings, coefficients of variation are computed with approximate 1% error (the errors of coefficients of variation of α and β estimators are 0.0588 and 0.1824, respectively). This error is obtained by computing with a fraction of the bootstrapping re-samplings (I used 100) several 'examples' of the coefficient of variation (30 examples), being the computation error the average standard error of these several examples divided by $\sqrt{30}$.

From the bootstrapping procedure it results as α and β estimators' inverse of the coefficients of variation 4.35 and 18.33, respectively.

Considering “ H_0 : the parameter is zero” in opposition to “ H_1 : the parameter is different from zero” and assuming that the estimator distribution is normal, the parameter is significant at a certain level when the inverse of the coefficient of variation is greater than the t - distribution critical value.

The normality hypothesis of α and β estimators may not be rejected from the data. Indeed, using the Kolmogorov-Smirnov test at a 10% level of significance (the Kolmogorov-Smirnov critical value is $0.0223 = 1.22/\sqrt{3000}$), observed α and β estimators' Kolmogorov-Smirnov statistics (0.0167 and 0.0193, respectively) are smaller than the corresponding critical value.

Testing the bilateral parameters significance at a 0.1% significance level (the critical value is 3.29), the hypothesis that α or β parameters are equal to zero can be rejected (both parameters are significant at a 0.1% significance level). In addition, one cannot reject the hypothesis that β parameter is equal to one (the value to test, $(\hat{\beta} - 1)/S$, is equal to 0.23). Parameter β being equal to one suggests that reviewers are identically exigent on the relevance of each page, maximizing the journals' citation potential.

VI. NON-LINEARITIES IN THE EFFECT OF THE NUMBER OF PAGES

One may test the existence of non-linearity by assuming an extended model where β evolves with the number of pages:

$$\beta = \beta_0 + \beta_1 \cdot \left(\frac{p_i}{\bar{p}_j} - 1 \right) \quad (9)$$

The result of the estimation is (the inverse of the coefficient of variation in parentheses):

$$\hat{\alpha} = 0.235 (5.03) \quad \hat{\beta}_0 = 1.068 (2,86) \quad \hat{\beta}_1 = 0.064 (0,14) \quad R^2 = 20.88\% \quad (10)$$

Being that the parameter β_1 is statistically non-significant, the data reinforces the assumption that the model (1) is adequate.

VII. CLASSIFICATION OF JOURNALS IN GROUPS

It is certain that journals do not have identical fixed-effects. Nonetheless, from table 2 one sees qualitatively that fixed-effects of those journals that are proximal in the ranking are not statistically different. This suggests that journals can be clustered in a limited number of groups.

The division of the journals in N groups is done by determining the ranking cut-off values (inclusive) that maximizes R^2 (see the example $N = 2$ in fig. 6).

Testing journals divided in 1, 2, 3 or 4 groups, the model's R^2 becomes 21.0%, 80.3%, 89.7% and 91.2% of the R^2 computed with 168 'groups', respectively. Using as condition to maintain 90% of the model's R^2 , it is adequate to consider journals divided in 4 groups (see table 1).

In table 1, the column "*G points*" scales the fixed effects to 100, turning easier to compare journals' groups. For example, a person that publishes a 3 co-authored 10 pages article in a B+ class journal, a 2 co-authored 12 pages article in a B class journal and a single-authored 15 pages article in a B- class journal sums up 420 points:

$$\frac{39,6 \cdot 3^{0.237} \cdot 10^{1.012}}{3} + \frac{19,2 \cdot 2^{0.237} \cdot 12^{1.012}}{2} + \frac{6,7 \cdot 2 \cdot 1^{0.237} \cdot 15^{1.012}}{1} = 420 \quad (11)$$

Even though I do not have data on the journals that are covered by the ISI database and have been excluded from the analyses, I propose that they should be classified as B– and credited 6,7 points to each single authored page.

It remains to evaluate the hypothesis that there are differences in the influence of the number of co-authors and pages between journals groups. To do this I estimate the model (1) for A class journals (17 journals) and for B– class journals (56 journals) and I compare the estimates.

$$\begin{aligned} \hat{\alpha}_A &= 0.260 (3.91) & \hat{\beta}_A &= 1.045 (14,89) \\ \hat{\alpha}_{B-} &= 0.368 (5.62) & \hat{\beta}_{B-} &= 0.812 (14,45) \\ \Delta\hat{\alpha} &= -0.108 (-1.15) & \Delta\hat{\beta} &= 0.233 (2.60)* \end{aligned} \quad (12)$$

Statistically there are significant differences in the effect of the number of pages (1% level), being rejected the hypothesis that B– journals pages elasticity is 1 (see fig. 7). This result reinforces the conjecture that B– journals publish fewer articles and with a larger number of pages than optimal.

VIII. CONCLUSION

In this work I validate that it is correct to correlate positively academics remuneration with the number of published articles per co-author, the number of pages and journal reputation although an increase in the number of co-authors causes a small increase in article value. For example, to each co-author of a two co-authored page, it would be more correct to credit value equivalent to 0,59 single authored pages. I have done the evaluation estimating a non-linear model with panel data from 168 economics journals covered by the ISI-Web of Knowledge database throughout

1986-1996. The model is estimated by minimizing the sum of the squares of deviations and I use bootstrap re-sampling to test estimates significance.

Additionally, relating to journals quality, data suggests that there are 4 distinct groups that I named A, B+, B and B-. The grouping of journals using a statistical measure is new in the literature.

Finally, the data reinforces the conjecture that, on average, reviewers maximize journals citation potential (citations/pages average elasticity is one) being that lower-ranking journals' reviewers are less capable of doing that (they accept fewer articles and with larger extension than optimal).

Upon request, the author provides used data and computer programs.
